NACA WARTIME REPORTS are reprints of papers originally issued to provide rapid distribution of advance research results to an authorized group requiring them for the war effort. They were previously held under a security status but are now unclassified. Some of these reports were not technically edited. All have been reproduced without change in order to expedite general distribution.

NACA ARR No. E4H22

ADVANCE RESTRICTED REPORT

PERFORMANCE TESTS OF NACA TYPE A FINNED-TUBE
EXHAUST HEAT EXCHANGER

By J. George Reuter and S. V. Manson

SUMMARY

Tests have been conducted to determine the thermal and pressure-drop performance and, to a limited extent, the durability of a cross-flow, internally finned, tubular exhaust-heat exchanger designed at the Aircraft Engine Research Laboratory. The tests covered a range of exhaust-gas flows from 3500 to 7000 pounds per hour, cooling-air flows from 3500 to 9500 pounds per hour, and exhaust-gas temperatures from 800° F to 1550° F. The exhaust gas was produced in a gasoline combustion furnace.

The test results show that this exchanger transfers 250,000 Btu per hour at an exhaust-gas flow of 4000 pounds per hour and a cooling-air flow of 3000 pounds per hour for an entrance-temperature difference of 1500° F between the exhaust gas and the cooling air. The corresponding pressure drop of the cooling air is 4.3 inches of water at standard sea-level density and of the exhaust gas, 2.5 inches of water at sea-level pressure and 1500° F entrance temperature. After 90 hours of operation the test unit gave no indication of deterioration.

INTRODUCTION

The exhaust-gas heat exchanger is of current interest as a means not only of providing heated air for aircraft de-icing and cabin heating but also of rendering the exhaust gas invisible by reducing its temperature. In the past few years a variety of designs have been constructed and tested largely under the sponsorship of the NACA. (See references 1 to 6.) The success of many of these investigations has created a growing interest in the general improvement of the exhaust-gas heat exchanger.

The problem of the design of an exhaust-heat exchanger is largely a question of selecting a core structure that combines

low pressure drops and lightness of weight with compactness and durability. Compactness is naturally limited by excessive pressure drops but it may be obtained to a higher degree with one core structure than with another of the same general type if proper consideration is given to the surface distribution. In any heat exchanger the heat dissipation per unit volume is maximum when the heat conductance on one side of the transfer surface is equal to that on the other side. If the heat-transfer surfaces and fluid velocities are such that these conductances are unequal, indirect transfer surface may be added to the inner side and the flow-passag dimensions adjusted to prevent prohibitive pressure drops. Furthermore, indirect transfer surface added to the cooling-air side is subjected to lower temperatures and hence is less likely to deteriorate.

On the basis of the foregoing considerations, a cross-flow tubular exhaust-heat exchanger in which cooling-air flows through the tubes was designed at the Aircraft Engine Research Laboratory of the NACA at Cleveland, Ohio, in the autumn of 1943. Within each tube are longitudinal, continuous fins welded to the inner wall by a process developed by the Brown Fin-Tube Company of Elyria, Ohio, who constructed the entire unit. The tube ends are welded into thin header plates in a manner intended to provide flexibility against thermal expansion. Tubular instead of plate-type construction was chosen because of its greater strength and lesser susceptibility to warping resulting from uneven heating.

The unit was laboratory tested at AERL during February and March 1944 for thermal and pressure-drop performance and, to some extent, for durability over a range of fluid flows and exhaust-gas temperatures. The results of these tests are presented herein in the form of tables and curves.

NACA TYPE A HEAT-EXCHANGER TEST UNIT

The details and general appearance of the NACA heat exchanger are shown in figures 1 and 2. The exchanger core consists of 45 low-carbon steel tubes inserted in thin header plates of the same material. The tubes are about 10 inches long and have an outer diameter of 0.75 inch with a wall thickness of 0.023 inch. Inside each tube eight continuous, longitudinal fins of low-carbon steel are welded, as shown in figure 1. The fins are 0.018 inch thick, 0.190 inch high, and equally spaced along the circumference. The use of stainless-steel material for the entire unit would be preferable but availability considerations prevented such choice.

The tubes are in staggered arrangement with exhaust-gas flow across seven banks of nine tubes each. These tubes are inserted into punched holes in the header plates and are flame-welded at the junction tips, as shown in figures 1 and 2. This construction should provide flexibility. The tube-end welds are exposed to the cooling-air flow and are shielded from the exhaust gas. This position of extended surface and welded joints should favor the durability of the exchanger.

The weight of this heat exchanger, as received from the factory and as shown in figure 2, was 25.5 pounds including flanges and rib-strengthened plates covering the no-flow faces. Before the exchanger was mounted for testing, the flanging was changed to provide a more convenient and leak-proof installation. The weight might be reduced by the use of thinner metal for tube walls and fins, but in this connection there is a question of durability that requires further investigation.

TEST SETUP

A diagram of the test setup is shown in figure 3. The test equipment consisted essentially of an exhaust-gas producer, the heat-exchanger test unit, ducting, flowmeters, and temperature- and pressure-measuring instruments. Both the cooling air and the air required for combustion were obtained from the laboratory combustion-air supply; the respective flows were controlled by pressure-regulated butterfly valves. The cooling air flowed through the tubes and the exhaust gas flowed across the tubes of the exchanger. Flow rates were measured upstream from the exchanger by means of calibrated thin-plate orifices installed according to A.S.M.E. specifications.

Entrance and exit fluid temperatures were measured by thermocouples placed across each flow section at distances from the core faces as shown by figure 4. Cooling-air temperatures were indicated on a self-balancing, direct-reading potentiometer; exhaust-gas temperatures were indicated on a manually balanced potentiometer. In the exhaust stream were quadruple-shielded chromel-alumel thermocouples, three at the entrance of the heat exchanger and three at the exit. One of each set of three was a General Electric thermocouple; the other two were constructed at this laboratory with a spiral shield of four turns. The readings obtained from the three thermocouples at each station were in good agreement. Unshielded iron-constantan thermocouples were used in the cooling-air stream, two at the upstream side of the exchanger and sets of six placed diagonally across each of two sections downstream from the exchanger.

The test unit was enclosed in an insulating cement 2 inches thick. The insulation was extended along each duct beyond all thermocouple stations to prevent error due to heat losses to the room. The entire duct between the exhaust-gas producer and the test unit was insulated in the same manner. Upstream of one of the downstream sections (station C) were mixing baffles, as indicated in figure 4. When the exhaust-gas temperature was high (1400° F to 1550° F) the indicated temperature at station C was about 4° F lower than the indicated temperature at station B. This difference in indicated temperatures decreased with exhaust-gas temperature and was, in all cases, less than 2 percent of the cooling-air temperature rise. Since the insulation on the duct walls prevented heat loss of sufficient magnitude to cause appreciable temperature drop, the difference in temperature indications between stations B and C is attributed to radiation from the downstream header plate of the exchanger to the thermocouples at station C. The thermocouples at station C could not be thus affected because of the shielding effect of the baffles and the intervening 90° elbow. The temperature rise was computed from temperatures obtained from stations A and C, because it was assumed that practically equal radiation effects existed at these two stations and that the error due to radiation would be canceled in the temperature difference.

Static pressures upstream and downstream from the exchanger were measured in both fluid streams for stations at distances from the core faces given in figure 4. At each station a pressure tap was installed at the center of each face of the rectangular section. The four taps of each section were connected through a piezometer ring to a manometer. Pressure-tap stations were between thermocouple stations and the exchanger.

TEST PROCEDURE

The tests consisted of 12 series of runs that involved a total of about 90 hours of testing time. In each series the fluid weight flows were kept as nearly constant as possible and the exhaust-gas entrance temperature was varied in increments of about 200° F by changing the amount of gasoline supplied to the exhaust-gas producer. The cooling-air inlet temperature, though not controlled, remained nearly constant at 65° F $\pm 10^{\circ}$ F throughout the tests. The fuel-air ratio of the exhaust gas varied from 0.014 to 0.025 depending on the exhaust-gas temperatures desired.

The approximate exhaust-gas flows, the approximate cooling-air flows, and the range of gas-inlet temperatures used are given in the following table:

Exhaust-gas flow rate, W_e (lb/hr)	Cooling-air flow rate, W_a (lb/hr)	Range of gas-inlet temperatures (in steps of approximately 200° F (°F))
3500	3500	1100 to 1500
	5400	800 to 1500
	7200	900 to 1500
	9300	900 to 1550
5400	3400	950 to 1500
	5400	1000 to 1500
	7400	850 to 1550
	9450	850 to 1350
7200	5700	1250 to 1500
	5150	1100 to 1500
	7100	1000 to 1500
	9400	900 to 1500

After the tests, the unit was checked for leakage under a pressure of ½ inches of mercury. No leaks were detected in the core proper but a slight leak was found in a welded joint in the casing near a flange. Under the leak-test pressure of ½ inches of mercury, the measured flow through this leak was about 0.001 pound per second.

All the important data obtained in these tests are summarized in table I.

All the symbols used in the analysis are defined below:

- c_p specific heat at constant pressure, $(Btu)/(lb)(^{\circ}F)$
- H rate of heat exchange between fluids, $(Btu)/(hr)$
- T fluid temperature, $(^{\circ}F)$
- r no-flow length, (in.)
- W weight flow, $(lb)/(hr)$
- P_{en} static pressure of fluid at entrance of exchanger, (in. Hg absolute)
- Δp pressure drop across exchanger, (in. H_2O)

ΔT temperature change of fluid across exchanger, ($^{\circ}$ F)

$\Delta T_e'$ temperature change of exhaust gas computed from heat balance equation, $[\Delta T_e' = \dot{W}_a c_{p_a} \Delta T_a / \dot{W}_e c_{p_e}]$

τ_e cooling effectiveness of exchanger, $\left[\frac{\Delta T_e'}{(T_e)_{en} - (T_a)_{en}} \right]$

τ_a heating effectiveness of exchanger, $\left[\frac{\Delta T_a}{(T_e)_{en} - (T_a)_{en}} \right]$

σ density of cooling air relative to standard atmospheric density of 0.0755, (lb)/(cu ft)

ρ_e density of exhaust gas, (lb)/(cu ft)

ρ_{eo} density of exhaust gas at 1500° F, 29.92 inches of mercury and a fuel-air ratio of 0.08, $[(0.0194 \text{ lb})/(\text{cu ft})]$

ex exit

RESULTS AND DISCUSSION

Thermal Performance

Figure 5 shows a plot of the heat dissipated by the exhaust gas against the heat absorbed by the cooling air. A value of 0.241 was used for the specific heat of the cooling-air and values ranging from 0.254 to 0.274 were used for the specific heat of the exhaust gas depending on the average temperature. The points in this figure were calculated from the relations

$$Q_a = \dot{W}_a c_{p_a} [(T_a)_{ex} - (T_a)_{en}]$$

and

$$H_e = W_e c_{pe} \left[(T_e)_{en} - (T_e)_{ex} \right]$$

The specific heat of exhaust gas was assumed the same as that of air because of the extreme leanness of the exhaust-gas mixtures. An excess of heat absorbed by the cooling air over that dissipated by the exhaust gas at the higher heat flows is shown in the figure. The cause of this discrepancy is probably in the exhaust-gas stream, and for this reason the thermal performance has been evaluated from measurements on the cooling-air side.

In figure 6 is shown the heat output of the heat exchanger plotted against cooling-air flow for exhaust-gas flows of 3500, 5400, and 7200 pounds per hour and for an entrance-temperature difference of 1500° F. These values of heat output are the values of heat absorbed by the cooling air as computed from test data obtained at an exhaust-gas entrance temperature of about 1500° F corrected to an entrance-temperature difference of 1500° F. The correction was made by means of the following relation:

$$(H_a)_{1500} = (H_a)_{test} \times \frac{1500}{(T_e)_{en} - (T_a)_{en}}$$

The corresponding temperature rise of the cooling air is shown in figure 7. Examination of figures 6 and 7 indicates a cooling-air temperature rise of 405° F and a heat output of 293,000 Btu per hour for an exhaust-gas flow rate of 7200 pounds per hour (corresponding to engine operation at approximately 1000 hp) and for a cooling-air flow of 3000 pounds per hour. At the same cooling-air flow but with an exhaust-gas flow of 4000 pounds per hour the cooling-air temperature rise is 350° F and the heat output is 255,000 Btu per hour.

The cooling and heating effectiveness of the exchanger as a function of the fluid flows is shown in figure 8. The heating effectiveness is defined as

$$\eta_a = \frac{\Delta T_a}{(T_e)_{en} - (T_a)_{en}}$$

Because the temperature measurements on the cooling-air side are considered more reliable than those on the exhaust-gas side, the cooling effectiveness is defined as

$$\eta_e = \frac{\Delta T_e'}{(T_{e_{en}} - T_{a_{en}})}$$

where

$$\Delta T_e' = \Delta T_a \times \frac{w_a(c_p)_a}{w_e(c_p)_e}$$

The expression for $\Delta T_e'$ is obtained from the heat-balance equation,

$$w_e(c_p)_e \Delta T_e' = w_a(c_p)_a \Delta T_a$$

Figure 8 is based on data for exhaust-entrance temperatures of 1530° F to 1550° F , but it should apply for entrance temperatures of $1530 \pm 200^{\circ}\text{ F}$ without serious error. The heat-transfer process is only slightly affected in this temperature range by the variation with temperature of the combination of physical properties of the fluids involved.

Pressure Drops

The correlation of cooling-air pressure-drop data is shown in figure 9. Because the pressure drop is not only a function of weight flow but also a function of density change, the experimental data are expressed in terms of $\sigma_{en} \Delta P_a / V_a^{1.92}$ and plotted against σ_{ex}/σ_{en} . The exponent 1.92 was derived from pressure-drop equations given in reference 7 and is validated by the lack of scatter shown in this correlation. The relationship thus established is exploited in figure 10 on logarithmic paper with the conventional coordinates and for various values of σ_{ex}/σ_{en} which, for the cooling air, are equal to or less than unity. The effect on pressure drop of the density change in the exchanger is seen to be quite appreciable.

Figures 11 and 12 pertain to the pressure drop of the exhaust gas across the exchanger and are analogous to figures 9 and 10, respectively. In this case the values of $(\rho_e)_{ex}/(\rho_e)_{en}$ are greater than unity for nonisothermal flow, because the density of the gas increases when it flows through the exchanger. Figure 11 shows a greater scatter of the test data than shown in figure 9.

for the cooling air; furthermore the exponent 2.1 of W_e , which was found to best fit the data, is greater than theory would indicate. No definite explanation can be offered for these conditions; however, during the tests it was noted that under some test conditions a whistling sound was produced by the flow of the exhaust gas across the exchanger tubes. This condition was attended by erratic behavior of the manometers that measured the pressure drop. Notwithstanding the foregoing considerations, it can be stated that the curves of figure 12 represent the test values of pressure drop within 0.5 inch of water.

Although the thermal and the pressure-drop performances shown in figures 6, 7, 8, 10, and 12 are given for the test exchanger with a no-flow length of 12.75 inches, the curves are, of course, applicable to any no-flow length of an otherwise identical exchanger if the heat output H_{test} and the fluid flows (W_e)_{test} and (W_a)_{test} are corrected according to the following relations:

$$H = H_{test} \times \frac{w}{12.75}$$

and

$$J = J_{test} \times \frac{w}{12.75}$$

where H and J correspond to any no-flow length w , in inches.

Illustration of the Use of Logarithmic Charts

In order to determine the cooling-air pressure drop across the exchanger from figure 10 when the thermal performance and the entrance temperature and pressure of the exchanger are known, it is necessary that the terms σ_{en} and σ_{ex}/σ_{en} be first evaluated. The value of σ_{en} is obtained from the known entrance temperature and pressure. The density ratio is obtained from the expression

$$\frac{\sigma_{ex}}{\sigma_{en}} = \frac{1 - \frac{\Delta p_a}{(p_a)_{en}}}{1 + \frac{\Delta T_a}{(T_a)_{en} + 460}} \quad (1)$$

Since the value of Δp_a is being sought, it is assumed equal to zero and the equation is solved for a first approximation of σ_{ex}/σ_{en} which when applied to figure 10 together with the known value of cooling-air flow gives a value of $\sigma_{en}\Delta p_a$. This value of $\sigma_{en}\Delta p_a$ is divided by σ_{en} to obtain a first approximation of Δp_a , which is substituted in equation (1) for a second approximation of σ_{ex}/σ_{en} . In actual practice the effect of Δp_a on σ_{ex}/σ_{en} is small except at high altitudes. Ordinarily, therefore, this process of successive approximation is limited to one or two repetitions.

The use of figure 10 in determining the cooling-air pressure drop is illustrated by an example in which it is assumed that the following operating conditions are known:

1. Cooling-air flow, pounds per hour	3000
2. Turbulent-gas entrance temp return, °F	1500
3. Turbulent-gas flow, pounds per hour	4000
4. Cooling-air entrance pressure, inches Hg	15
5. Cooling-air entrance temperature, °F	45

The cooling-air pressure drop is determined as follows:

6. From items 4 and 5 and definition of σ

$$C_{2n} = \frac{15}{29.9} \times \frac{519}{505} = 0.516$$

7. from stages 1 and 3 and figure 7:

$$T_2 = 360^{\circ} \text{ F}$$

b. To obtain a first approximation for $\sigma_{\text{ev}}/\sigma_{\text{ph}}$, Δp_a is assumed equal to zero. Then from items 5 and 7 and equation (1):

$$\frac{\sigma_{\text{ex}}}{J_{\text{in}}} = \frac{1}{1 + \frac{2.50}{1.15 + 1.60}} = 0.590 \text{ (first trial)}$$

2. From items 1 and 5 and Figure 10:

$J_{pA2B} = 4.2$ inches of water

10. From items 6 and 9:

$$\Delta p_a = \frac{4.2}{0.516} = 8.1 \text{ (first trial)}$$

11. A second approximation of σ_{ex}/σ_{en} can now be obtained from items 4, 5, 7, and 10 and equation (1).

$$\frac{\sigma_{ex}}{\sigma_{en}} = \frac{1 - \frac{8.1}{15 \times 13.6}}{1 + \frac{350}{45 + 460}} = \frac{0.960}{1.694} = 0.567 \text{ (second trial)}$$

12. From items 1 and 11 and figure 10:

$$\sigma_{en}\Delta p_a = 1.3 \text{ inches of water}$$

13. From items 6 and 12:

$$\Delta p_a = \frac{1.3}{0.516} = 1.3 \text{ (second trial)}$$

It is obvious that further repetition is unnecessary.

The procedure to be followed in the use of figure 12 to obtain the exhaust-gas pressure drop is similar to that followed in obtaining the cooling-air pressure drop from figure 10. The exit-to-entrance density-ratio relationship for the exhaust-gas side of the exchanger differs from that for the cooling-air side and is expressed as follows:

$$\frac{(\rho_e)_{ox}}{(\rho_e)_{en}} = \frac{1 - \frac{\Delta p_e}{(p_e)_{en}}}{1 - \frac{\Delta T_e}{(T_e)_{en} + 460}}$$

SUMMARY OF RESULTS

1. The thermal output of the NACA Type A exhaust-heat exchanger was 255,000 Btu per hour at a cooling-air flow of 3000 pounds per hour and an exhaust-gas flow of 4000 pounds per hour. The pressure drops, under these conditions, were 4.7 inches of water for the cooling air at sea-level density (0.0765 lb/cu ft) and 2.5 inches of water for the exhaust gas at 1500° F and 29.92 inches of mercury.
2. After 90 hours of operation the heat exchanger, although constructed of low-carbon steel, showed no signs of failure from thermal stress imposed by exhaust temperatures up to 1500° F .
3. There were no indications after the tests that tubes of thinner walls could not have been used and the weight reduced from the present value of 25.5 pounds.

NATIONAL ADVISORY
COMMITTEE FOR AERONAUTICS

TABLE I - Concluded

SUMMARY OF TEST DATA ON NACA TYPE A HEAT EXCHANGER - Concluded

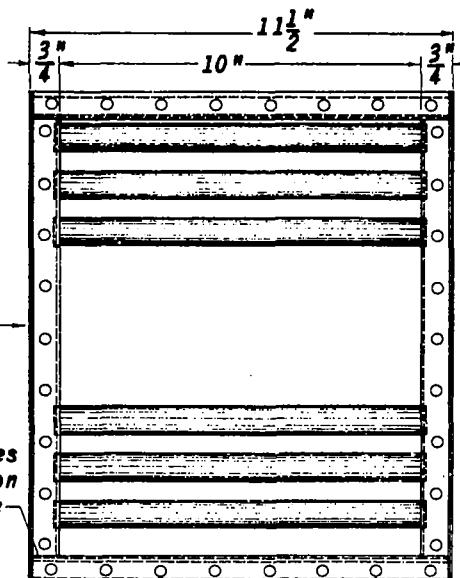

Cooling-air flow rate, W_a (lb/hr)	Cooling-air temperature			Heat added to cooling air, H_a (Btu/hr)	Exhaust-gas flow rate, W_e (lb/hr)	Exhaust-gas temperature			Specific heat of exhaust gas, c_{pe} (Btu/lb °F)	Heat rejected by exhaust gas, H_e (Btu/hr)	Heat-balance ratio, H_e/H_a	Heating effectiveness, η_a (percent)	Temperature change of exhaust gas, $\Delta T_e'$ (°F)	Cooling air inlet pressure, $(P_a)_{in}$ (in. Hg absolute)	Cooling air pressure drop, ΔP_a (in. Hg)	Exhaust-gas inlet pressure, $(P_e)_{in}$ (in. water)	Exhaust-gas pressure drop, ΔP_e (in. Hg)	Ratio of exhaust-gas exit and entrance den-sities, $(P_e)_{ex}/(P_e)_{in}$	Pressure drop of cooling air and entrance den-sities, $\frac{P_e}{P_a} \Delta P_a$ (in. water)	Pressure drop of exhaust gas, $P_e \Delta P_e$ (in. water)		
	At entrance, $(T_a)_{en}$ (°F)	At exit, $(T_a)_{ex}$ (°F)	Rise, ΔT_a (°F)			At entrance, $(T_e)_{en}$ (°F)	At exit, $(T_e)_{ex}$ (°F)	Drop, ΔT_e (°F)

NACA ARR No. E4H22

Fig. 1a,b,c,d

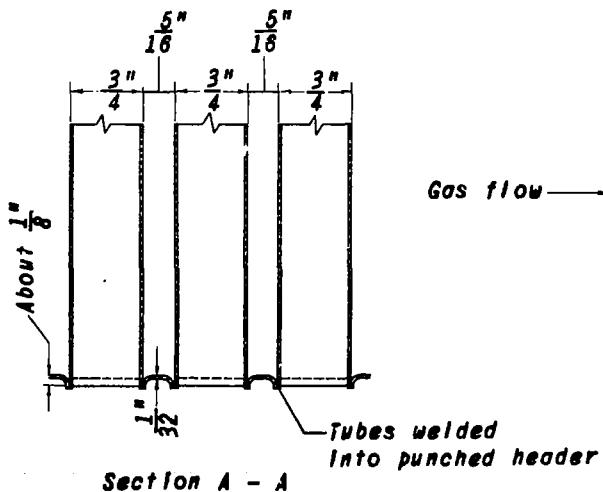

(a) Cooling-air face.

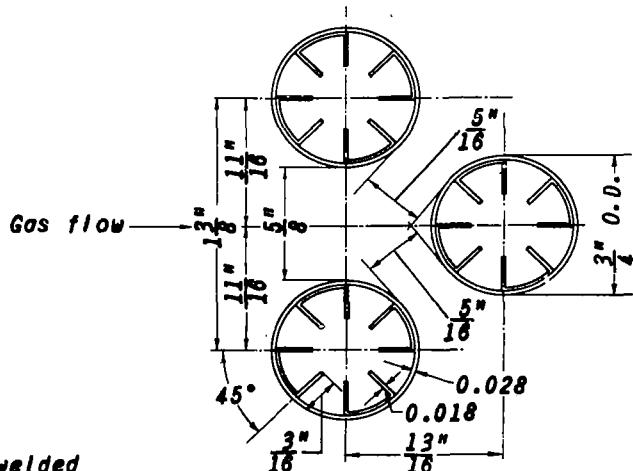

(b) Exhaust-gas face.

NATIONAL ADVISORY
COMMITTEE FOR AERONAUTICS

(c) Header-plate detail.

(d) Tube-spacing and finned-tube detail.

Figure 1. - Sketch of NACA type A heat-exchanger details.

NACA ARR No. E4H22

Fig. 2

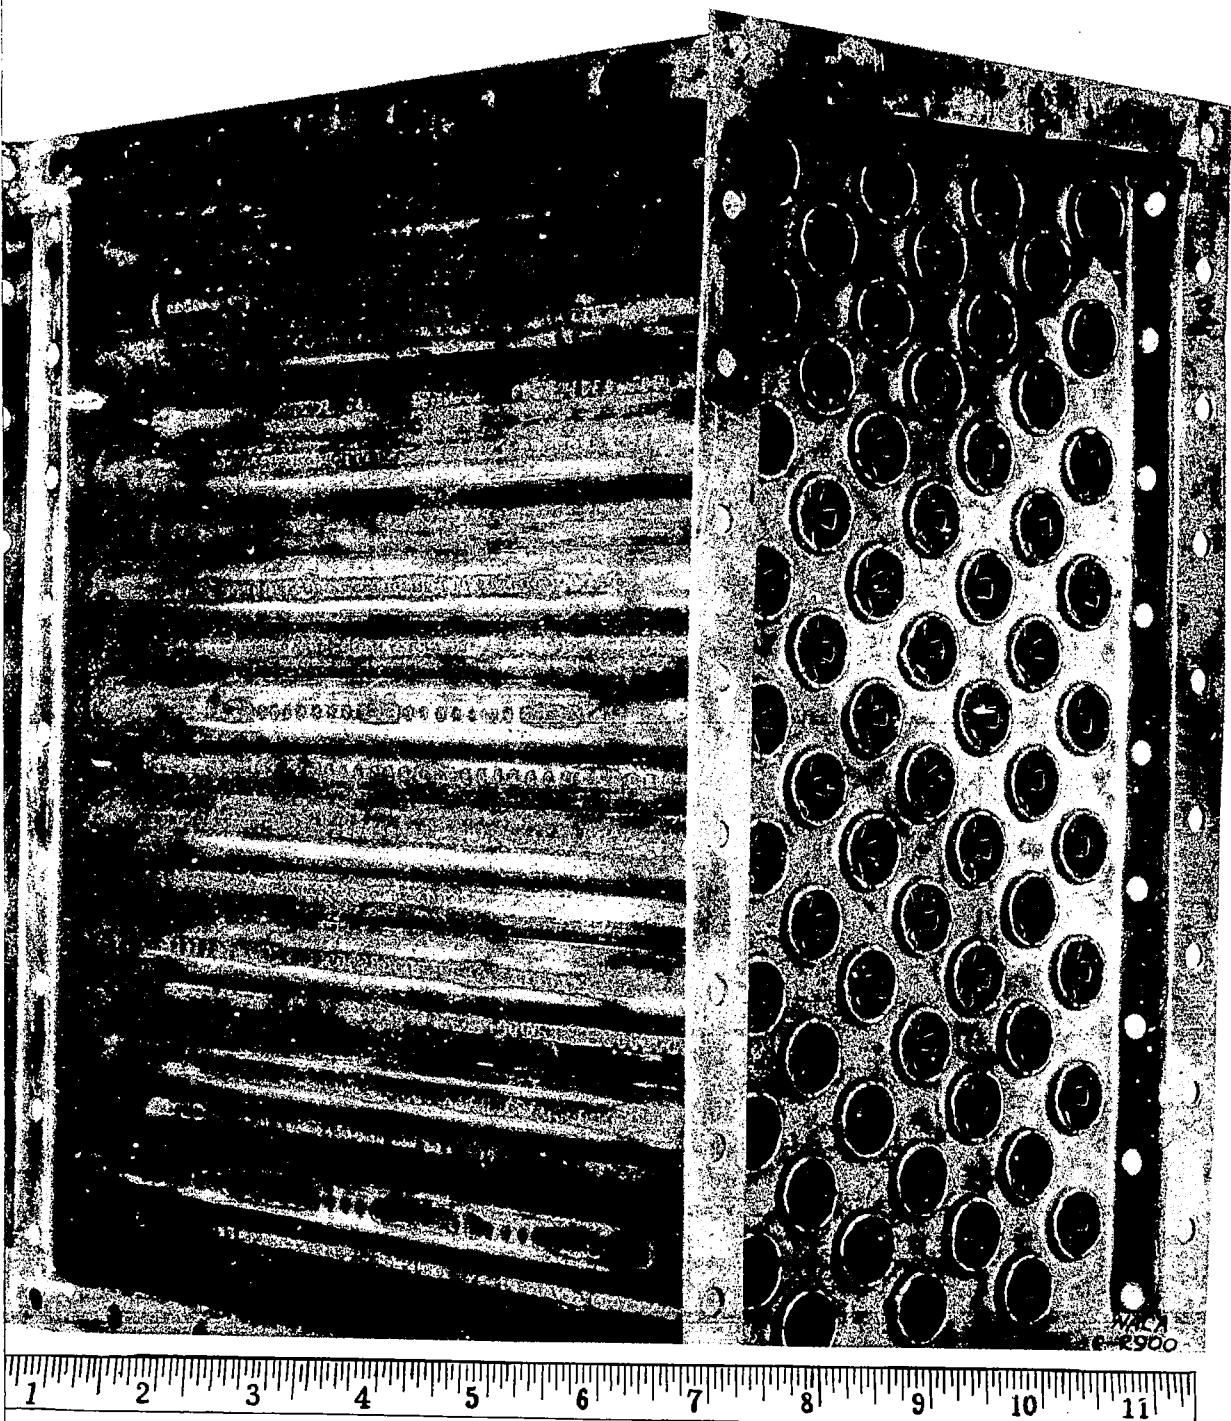

Figure 2. - The NACA type A internally finned tubular exhaust-heat exchanger.

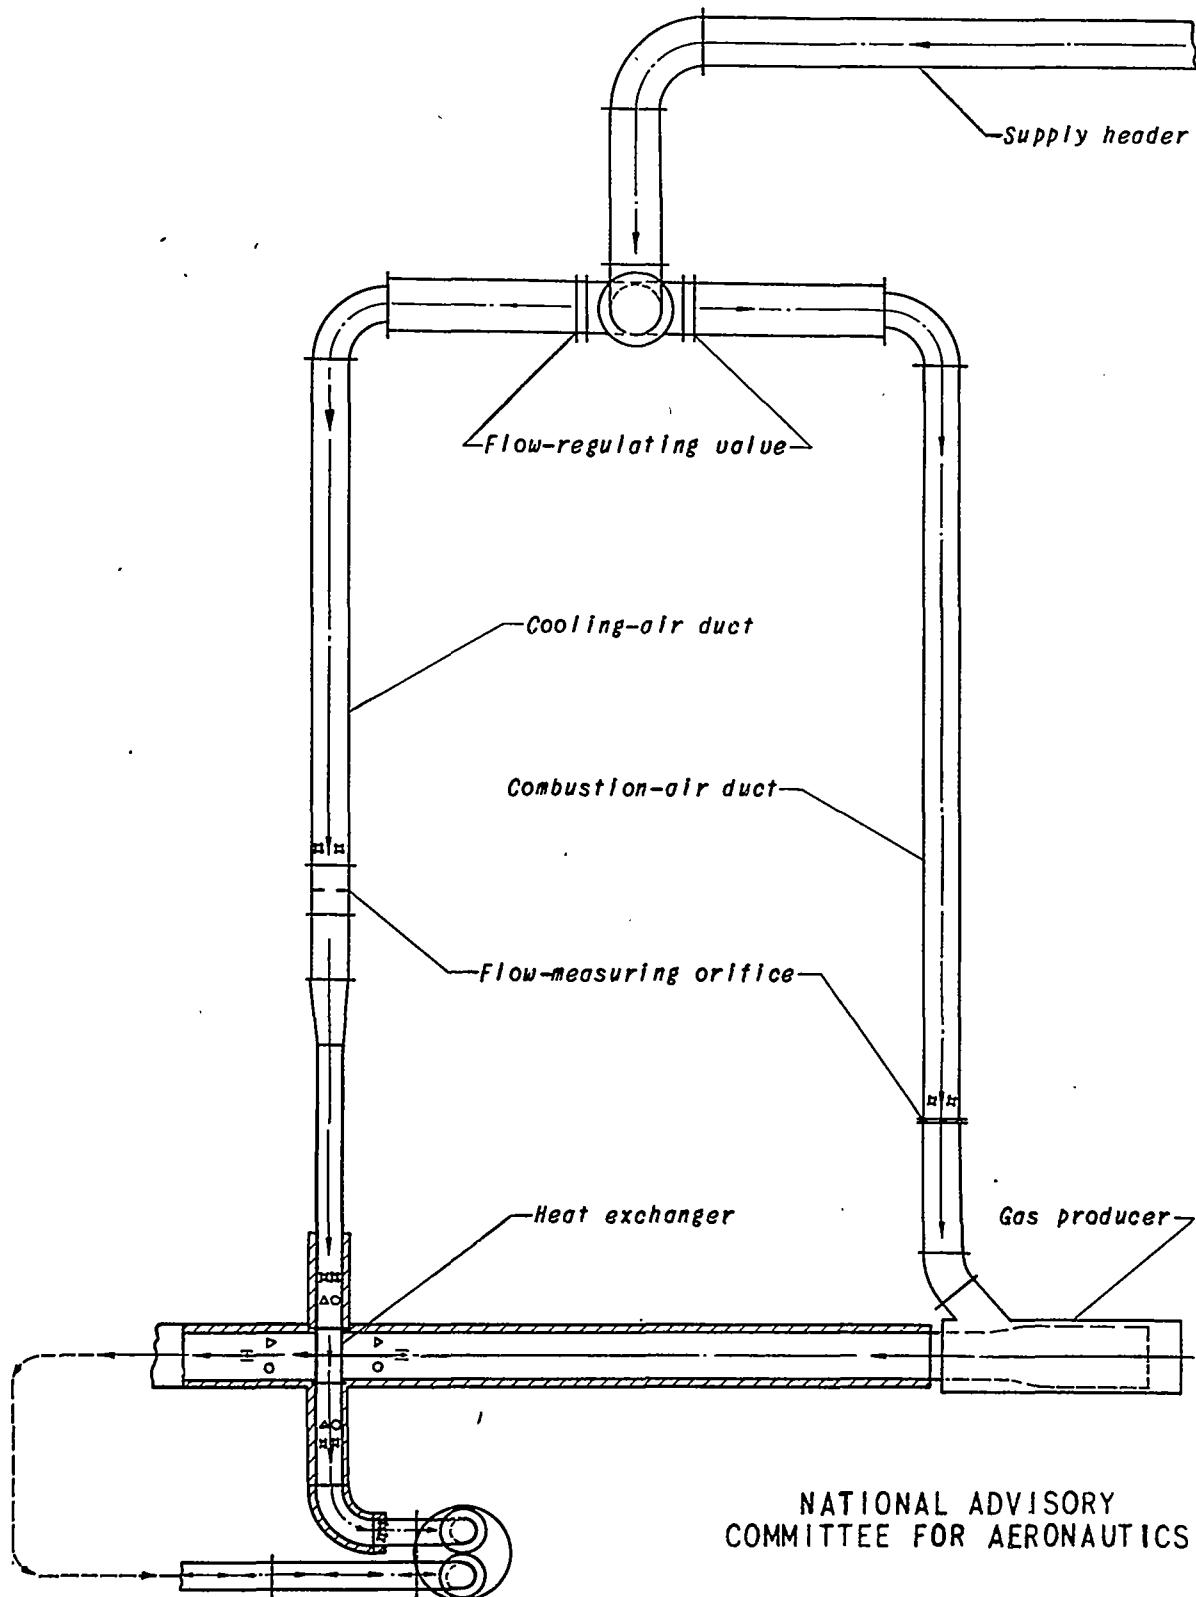

Figure 3. - Diagram of test equipment.

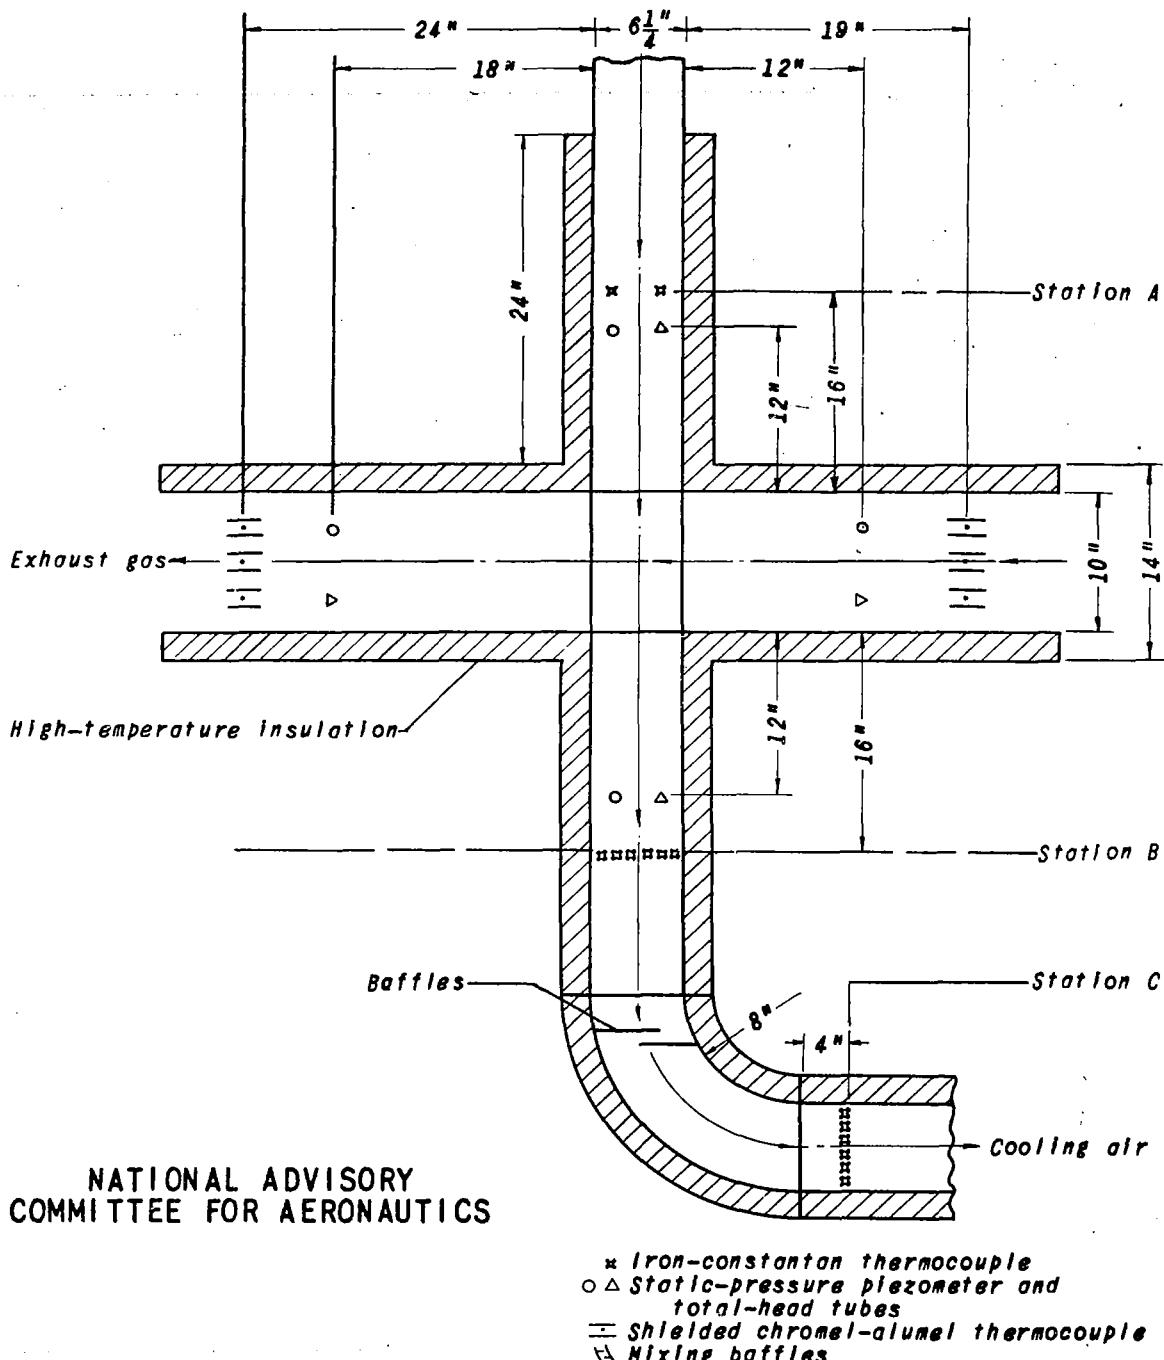

Figure 4. - Diagrammatic sketch showing positions of thermocouples, pressure taps, and baffle plates in heat-exchanger duct.

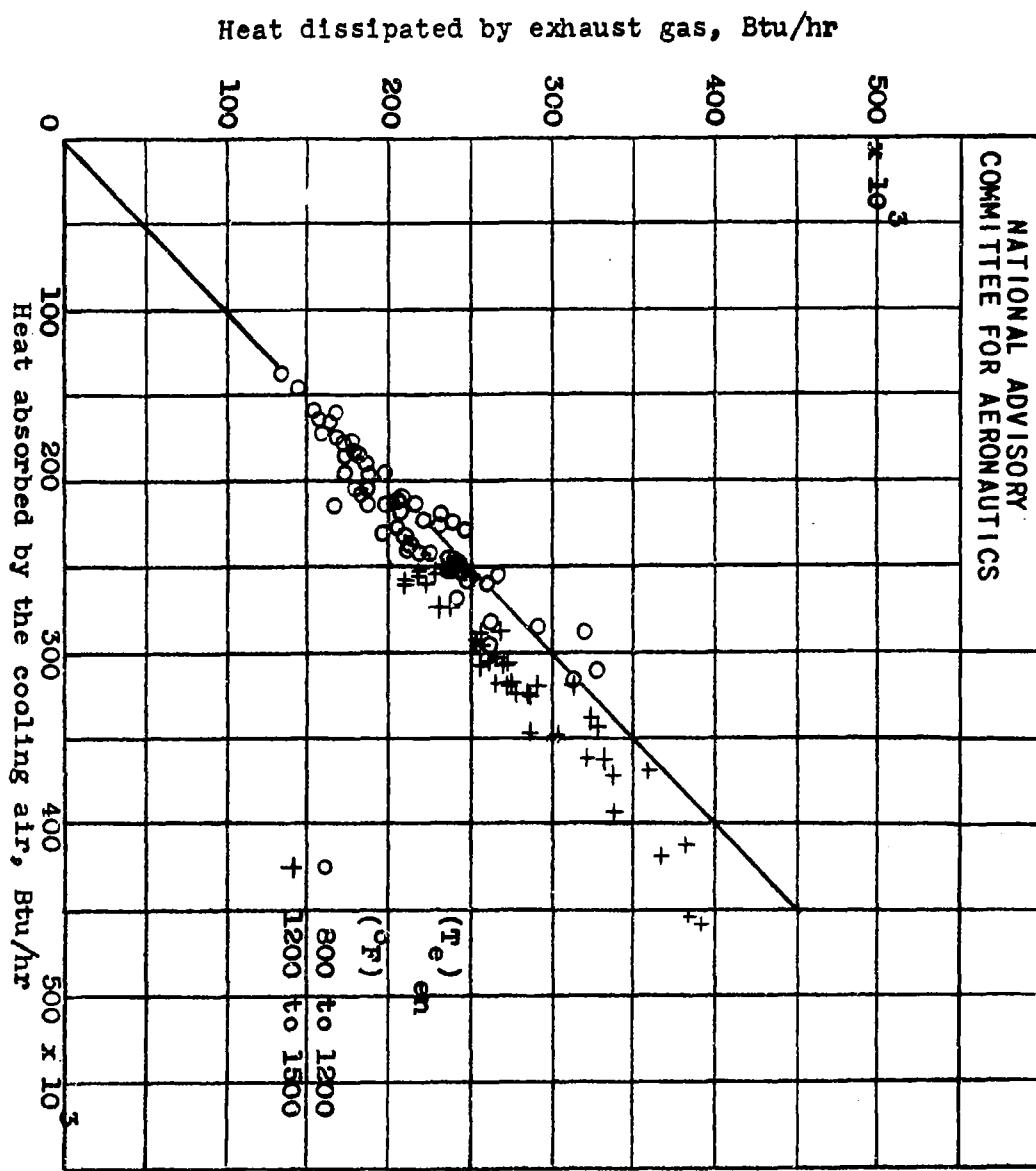

Figure 5.— Heat balance of cooling air and exhaust gas.

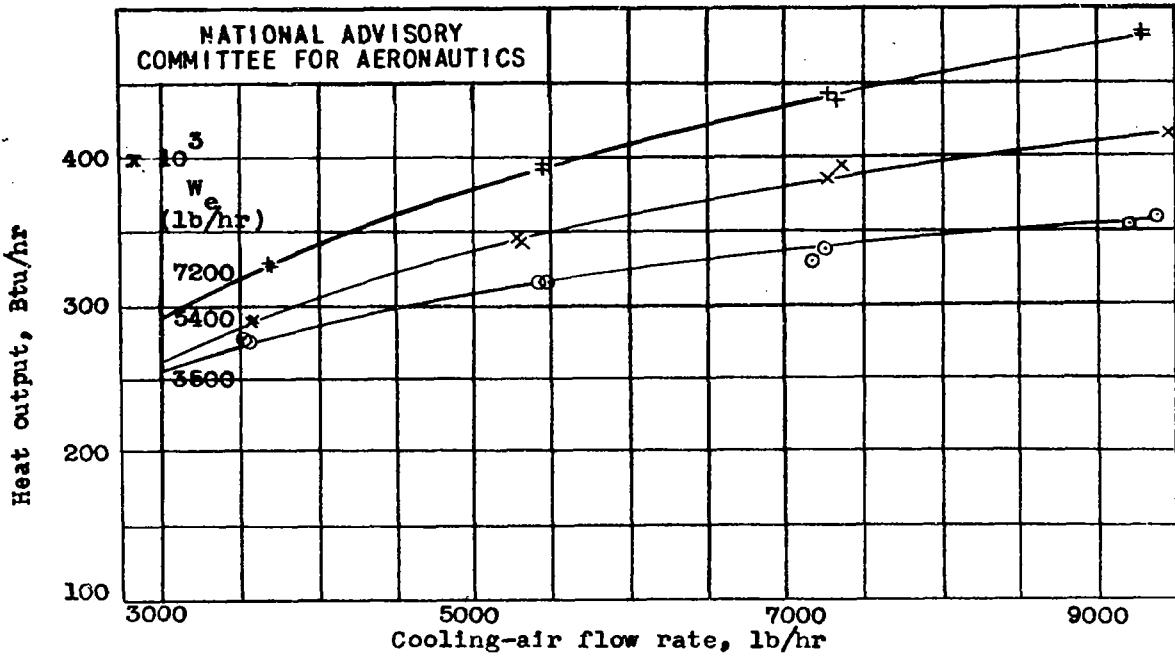

Figure 6.— Heat output of the NACA type A heat exchanger. Entrance-temperature difference, 1500°F .

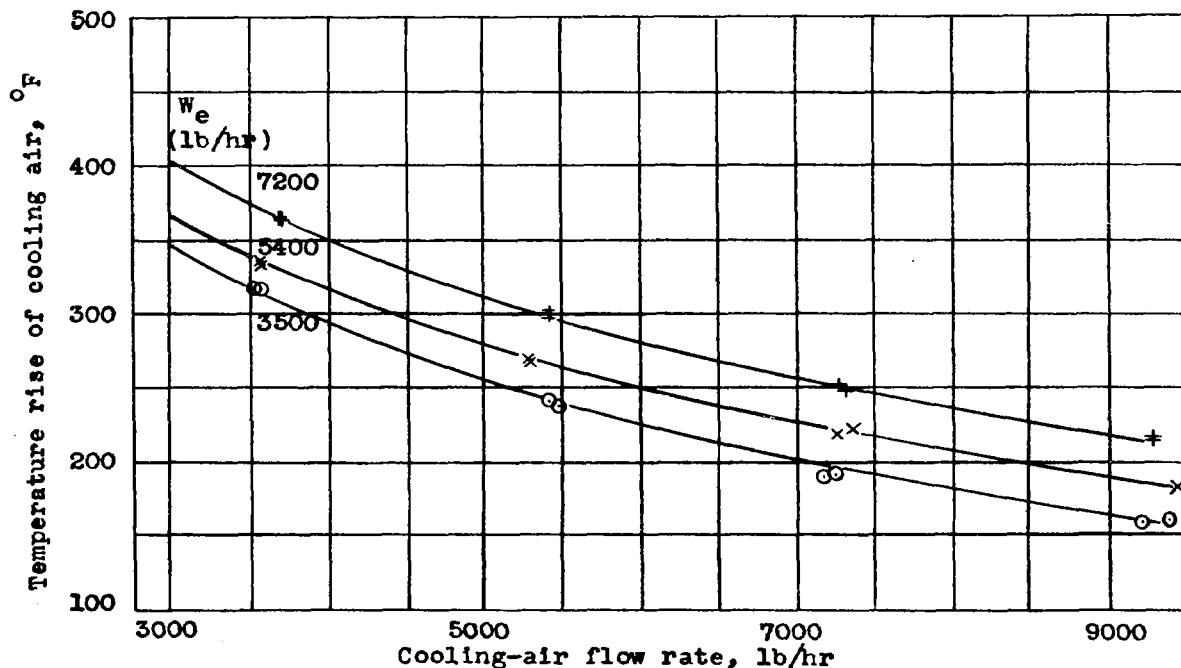

Figure 7.— Cooling-air temperature rise in the NACA type A heat exchanger. Entrance-temperature difference, 1500°F .

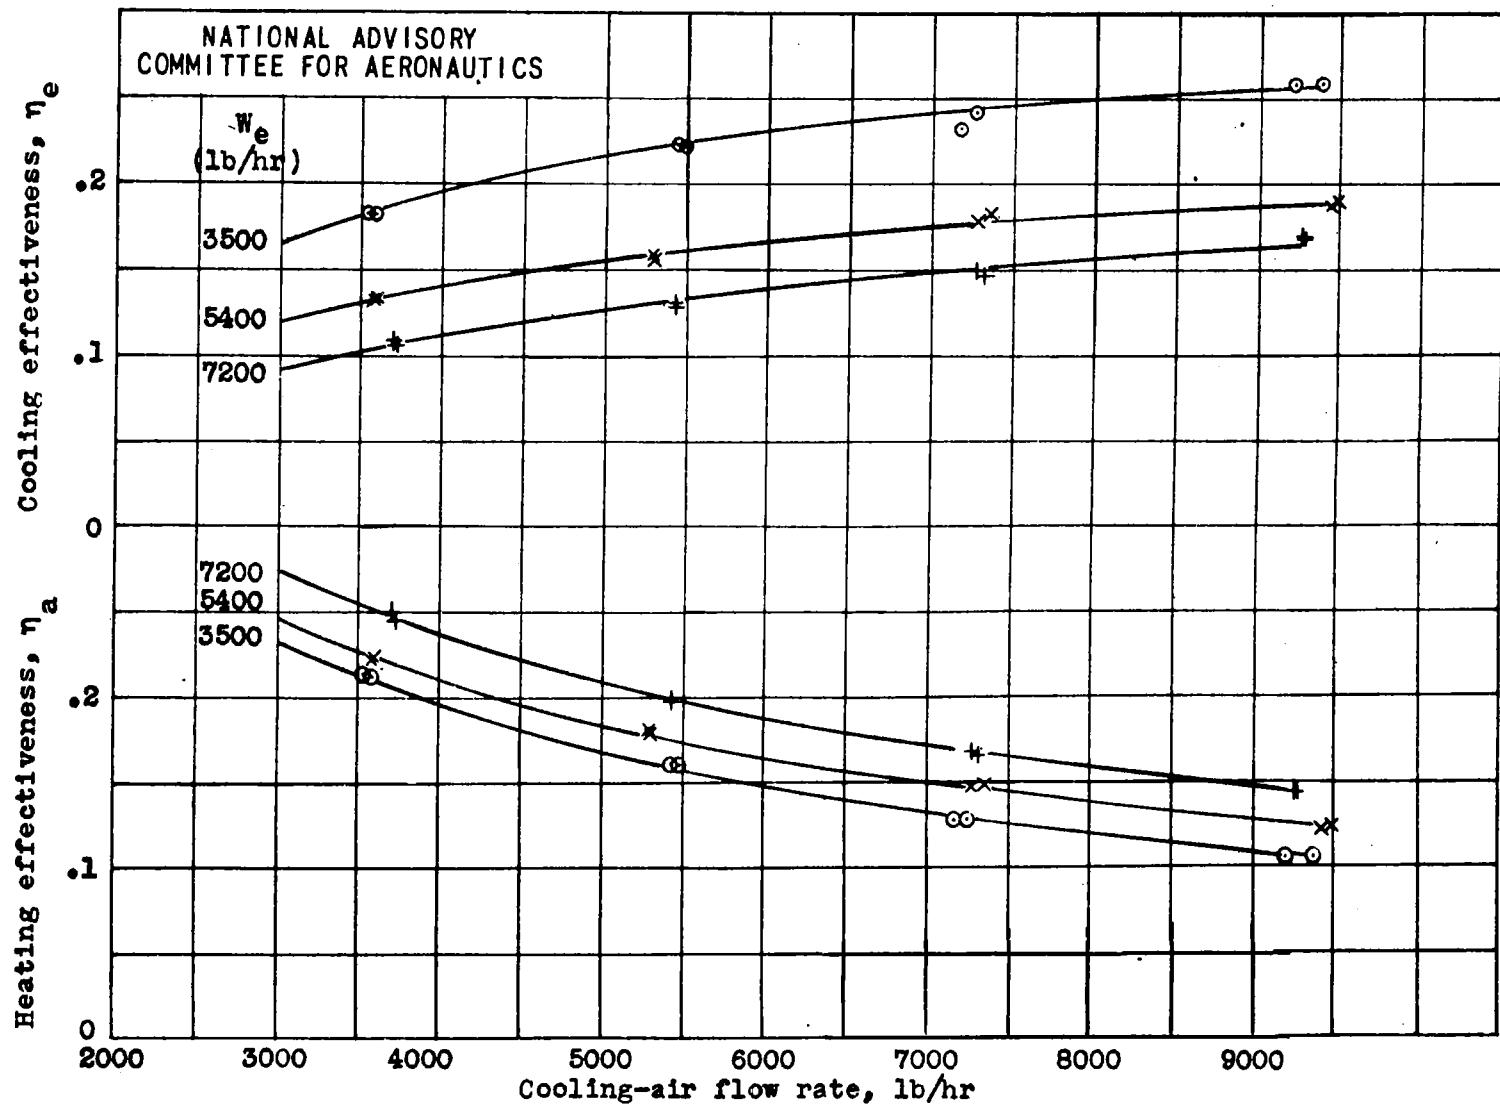

Figure 8.- Cooling and heating effectiveness of the NACA type A heat exchanger.

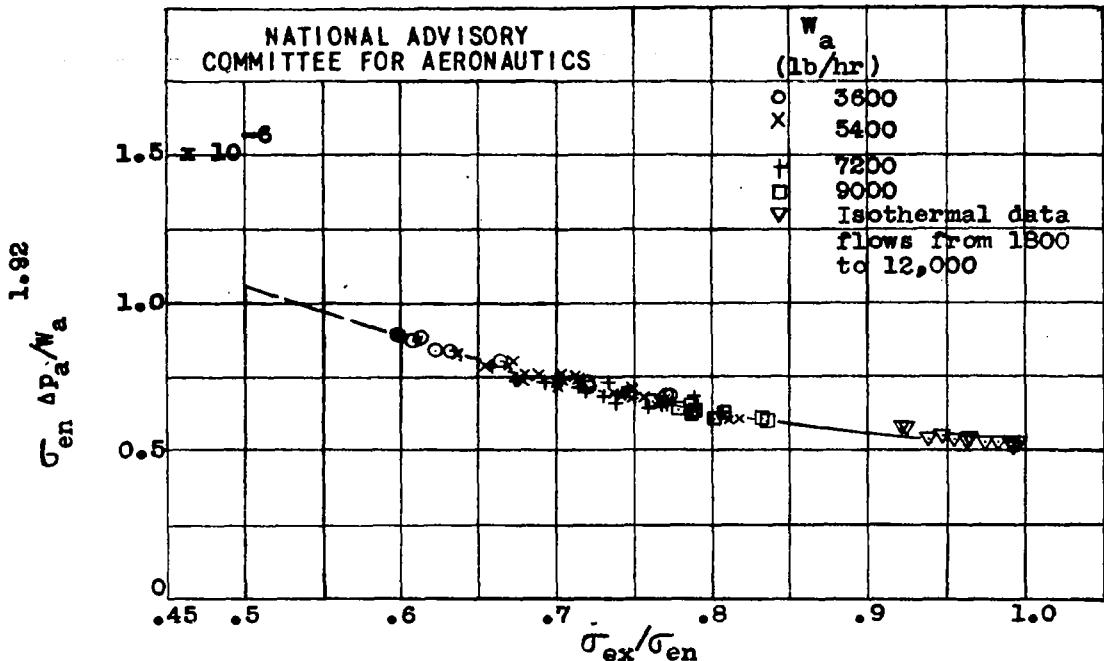

Figure 9.- Correlation of cooling-air pressure-drop data.

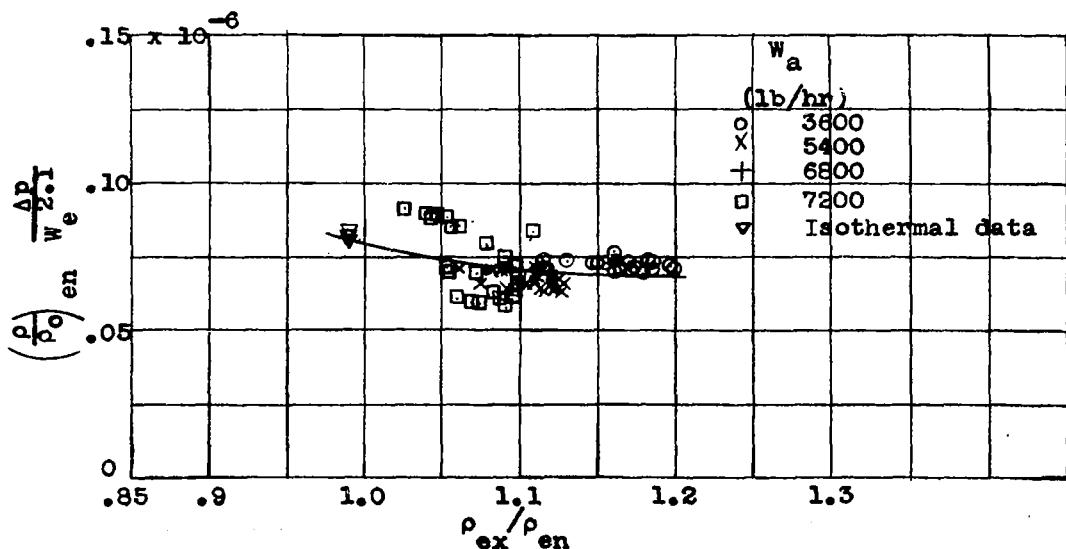

Figure 11.- Correlation of exhaust-gas pressure drop data.

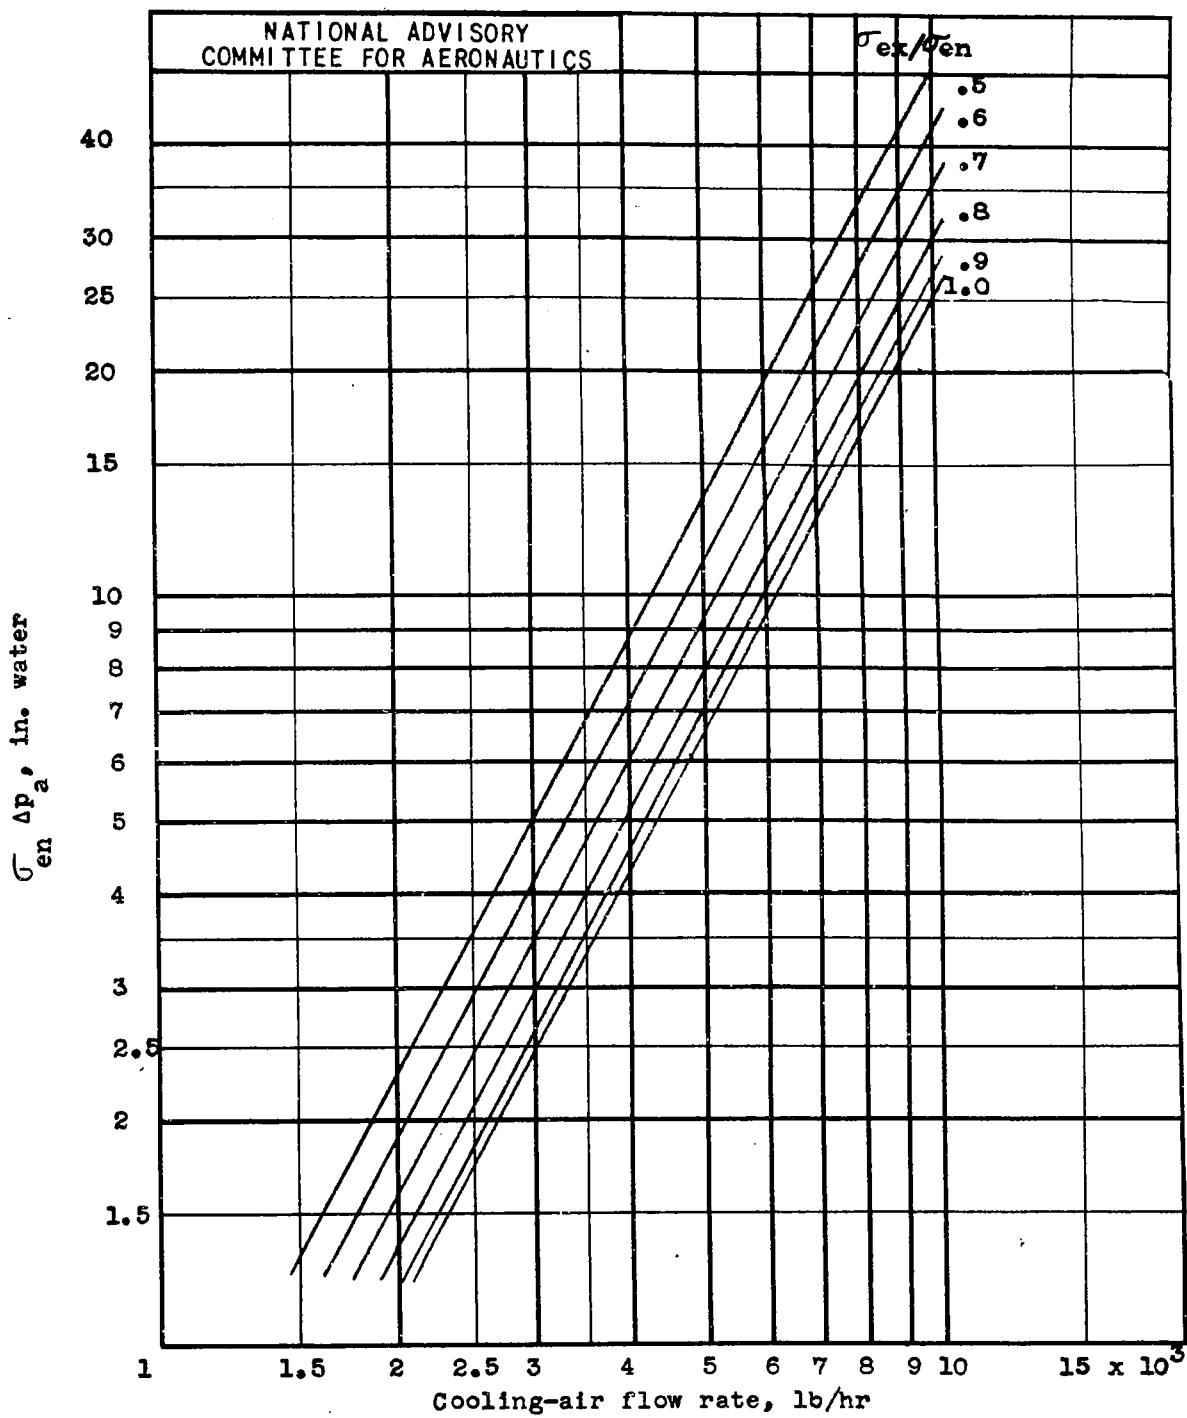

Figure 10.— Pressure drop of cooling air across the NACA type A internally finned tubular heat exchanger.

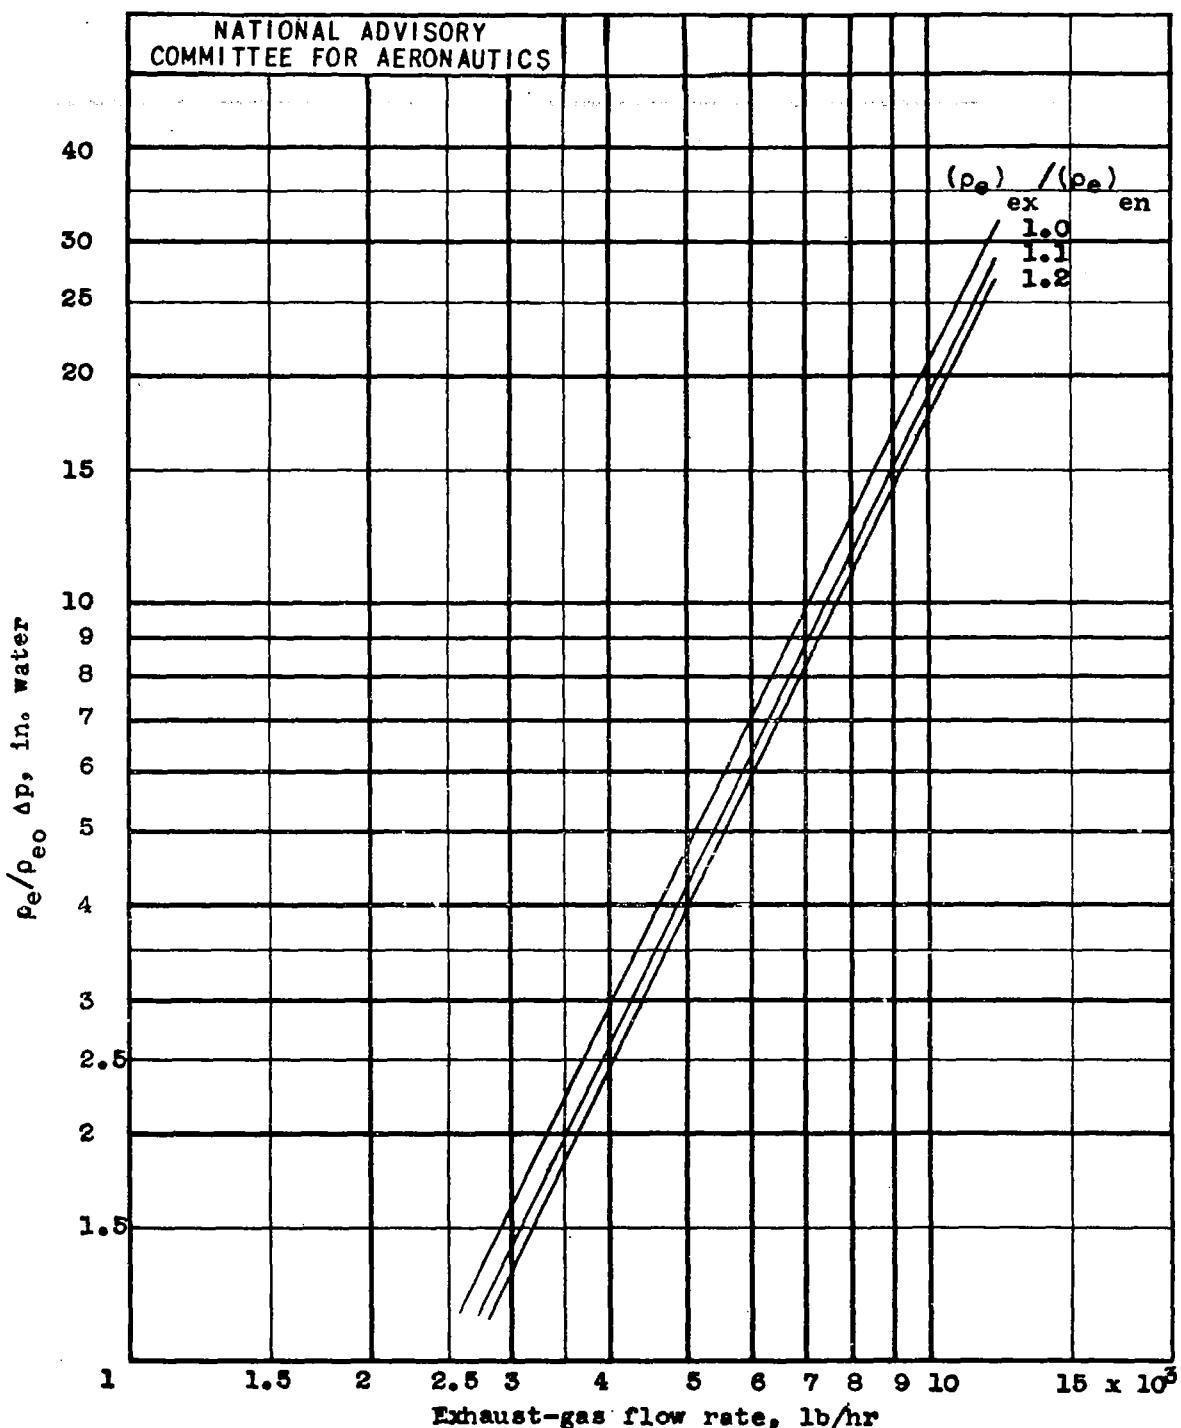

Figure 12.— Exhaust-gas pressure drop across the NACA type A internally finned tubular heat exchanger.
